Abstract

Hepatocellular carcinoma (HCC) development entails changes in liver metabolism. Current knowledge on metabolic perturbations in HCC is derived mostly from case-control designs, with sparse information from prospective cohorts. Our objective was to apply comprehensive metabolite profiling to detect metabolites whose serum concentrations are associated with HCC development, using biological samples from within the prospective European Prospective Investigation into Cancer and Nutrition (EPIC) cohort (>520 000 participants), where we identified 129 HCC cases matched 1:1 to controls. We conducted high-resolution untargeted liquid chromatography-mass spectrometry-based metabolomics on serum samples collected at recruitment prior to cancer diagnosis. Multivariable conditional logistic regression was applied controlling for dietary habits, alcohol consumption, smoking, body size, hepatitis infection and liver dysfunction. Corrections for multiple comparisons were applied. Of 9206 molecular features detected, 220 discriminated HCC cases from controls. Detailed feature annotation revealed 92 metabolites associated

with HCC risk, of which 14 were unambiguously identified using pure reference standards. Positive HCC-risk associations were observed for N1-acetyl spermidine, isatin, *p*-hydroxyphenyllactic acid, tyrosine, sphingosine, L,L-cyclo(leucylprolyl), glycochenodeoxycholic acid, glycocholic acid and 7-methylguanine. Inverse risk associations were observed for retinol, dehydroepiandrosterone sulfate, glycerophosphocholine, γ -carboxyethyl hydroxychroman and creatine. Discernible differences for these metabolites were observed between cases and controls up to 10 years prior to diagnosis. Our observations highlight the diversity of metabolic perturbations involved in HCC development and replicate previous observations (metabolism of bile acids, amino acids and phospholipids) made in Asian and Scandinavian populations. These findings emphasize the role of metabolic pathways associated with steroid metabolism and immunity and specific dietary and environmental exposures in HCC development.

KEYWORDS

hepatocellular carcinoma, prospective observational cohort, untargeted metabolomics

1 | INTRODUCTION

Primary liver cancer is the second most common cause of death from cancer worldwide.¹ Established risk factors for hepatocellular carcinoma (HCC), the major histology of primary liver cancers, are chronic hepatitis infection, aflatoxin exposure, smoking and alcohol abuse,² but obesity, diabetes and unhealthy dietary and lifestyle habits are also becoming increasingly recognized as important HCC-risk factors, particularly in regions where hepatitis infection and aflatoxin exposures are less predominant.³ HCC cases are often diagnosed at late stages and have limited treatment options, which is worrisome owing to the growing incidence of this highly fatal disease in many populations.⁴ It has been suggested that high obesity and diabetes rates in some populations are major contributors to the observed incidence rate increases.⁵ Most HCC cases are considered to develop within a background of inflammation, liver damage and cirrhosis. However, a sizeable proportion is thought to develop in the absence of underlying cirrhosis, hence escaping traditional clinical surveillance particularly in populations with lower prevalence of hepatitis infection and alcohol abuse, and higher prevalence of metabolic syndrome and nonalcoholic fatty liver disease (NAFLD), which are largely obesity related.^{6,7} Obesity may also impair the detection of cirrhosis or HCC by reducing the sensitivity of abdominal ultrasound, a primary tool for HCC surveillance in high-risk populations.⁸ Thus, effective HCC control will need to rely on strategies for both primary prevention and early detection, necessitating additional research into HCC etiology.

Decreased liver functionality is considered an early event in liver cancer development and given the central metabolic role of the liver various metabolic perturbations are very likely to be observed in blood. In addition, circulating biomarkers indicative of various lifestyle or environmental exposures that may affect HCC risk are also likely observable.⁹ Such metabolic signatures can be identified via various

What's new?

Changes in liver function precede the development of hepatocellular carcinoma (HCC). Many of these changes can be detected in the blood, as can biomarkers related to lifestyle or environmental exposures that may affect HCC risk. In this study, based on a large, prospective observational cohort, the authors used high resolution mass spectrometry-based metabolomics to identify alterations in circulating levels of 92 metabolites associated with HCC risk, 14 of which could be annotated with high confidence and some of which were observed up to 10 years prior to diagnosis. These results offer insight into early metabolic perturbations and mechanisms leading to this deadly cancer.

metabolomic techniques, such as those based on high-resolution liquid chromatography mass spectrometry (LC-MS), which may be applied to blood samples to observe a broad spectrum of low-molecular-weight compounds, which may be reflective of various exogenous exposures and associated with normal endogenous processes or perturbed metabolic functionality. In fact, several animal and human studies have already shown that metabolomics can provide novel insights into pathological processes during development of various liver diseases,^{10,11} and provide potentially novel diagnostic biomarkers of HCC for screening in high-risk populations.¹²⁻¹⁴ Most of the studies that have applied metabolic profiling in HCC have been either based on case-control designs, or conducted on high-risk patient groups (eg, viral hepatitis, cirrhosis or other chronic liver diseases), or in populations where more traditional HCC-risk factors predominate.¹⁵ However, comparatively very little information is available from prospective, observational cohorts about possible metabolic alterations

related to HCC development, particularly from European or Western populations.^{16–18} Information derived from prospective observational cohorts is important because data and biological samples have been collected from healthy participants before diagnosis, thus reducing the biases of recall and reverse causality and allowing considerable insight into the complex processes of cancer development. For example, within the European Prospective Investigation on Cancer and Nutrition (EPIC) cohort, a number of targeted metabolomic studies (ie, the measurement of defined groups of characterized and annotated metabolites; about 150 metabolites measured) have been conducted to assess metabolite patterns associated with risk of several cancers such as the breast¹⁹ and prostate,^{20,21} as well as with various lifestyle factors, such as body mass index²² and select dietary components.²³ They have revealed important insights on development processes and exogenous exposures associated with these cancers. Similar metabolomics techniques have also been applied in other prospective studies to explore cancer development at various anatomical sites, including HCC.^{18,24–26} We have also previously conducted two other metabolomics studies on HCC-risk factors in the EPIC cohort using nuclear magnetic resonance (NMR) spectroscopy¹⁷ and a targeted kit-based LC-MS assay.¹⁶ We observed alterations in amino acid, lipid and carbohydrate metabolism associated with HCC development, but our findings provided little new insight into HCC etiology or specific environmental exposures potentially linked to HCC development, due in large part to the low sensitivity of NMR¹⁷ and the limited number of metabolites measured with the kit-based assay.¹⁶

In the present study, our objective was to delve more deeply into an exploration of metabolic perturbations in HCC development through application of untargeted metabolomics (ie, the comprehensive analysis of all measurable analytes, but requiring intensive efforts toward metabolite annotation) using a highly sensitive LC-MS technique able to detect thousands of metabolites in typical blood samples²⁷ using a case-control design nested within the prospective EPIC cohort.

2 | MATERIALS AND METHODS

2.1 | Study design

The rationale and study design of the large multicenter prospective, observational EPIC cohort have been previously described.²⁸ Briefly, between 1991 and 2000, more than 520 000 apparently healthy men and women aged 20 to 85 years were recruited in 23 centers throughout 10 countries (Denmark, France, Germany, Greece, Italy, the Netherlands, Norway, Spain, Sweden, and the United Kingdom). At recruitment, standardized dietary, lifestyle and socio-demographic questionnaires, blood samples and anthropometric measurements were collected from most participants.²⁹ Blood samples are stored at the International Agency for Research on Cancer (IARC-WHO, Lyon, France) in -196°C liquid nitrogen for all countries except Denmark (-150°C , nitrogen vapor) and Sweden (-80°C , freezers), where they are stored locally.

2.2 | Nested case-control study

From 477 206 eligible participants, we included 129 HCC cases (diagnosed postrecruitment into the cohort and identified up to December 2010) with available baseline (ie, prediagnostic) blood samples. The cases were followed up for a median of 6.2 years/mean of 5.9 years from baseline recruitment until HCC diagnosis. For each case, we selected one control ($n = 129$) by incidence density sampling from all eligible cohort participants alive and matched by age at blood collection (± 1 year), sex, study center, time of the day at blood collection (± 3 hours), fasting status at blood collection (<3 , $3\text{--}6$ and >6 hours), and additionally among women by menopausal status (pre-, peri- and postmenopausal) and hormone replacement therapy use at time of blood collection (yes/no). Incidence density sampling for control selection is a common method of choice for unbiased results in case-control studies nested within a prospective cohort.³⁰ The method involves matching each case to a sample of those who are at risk from within the cohort population at the time of case occurrence.

HCC was defined as C22.0 according to the 10th revision of the International Statistical Classification of Diseases, Injury and Causes of Death (ICD10), with morphology codes “8170/3” or “8180/3” according to the second edition of the International Classification of Diseases for Oncology (ICD-O-2). For each case identified, the histology and diagnostic methods were reviewed by a trained pathologist to exclude metastatic cases or other types of primary liver cancers. Details on participant exclusion criteria and cancer incidence determination are described in the Supplementary Materials and Methods.

2.3 | Untargeted metabolomics

Detailed methods for the metabolomics analyses (ie, sample preparation and analysis, data preprocessing and feature identification) are provided in the Supplementary Materials and Methods. Briefly, samples were analyzed with a ultra-high performance liquid chromatography-quadrupole time-of-flight mass spectrometry (UHPLC-QTOF-MS) system (Agilent Technologies, Santa Clara, CA) using four different analytical configurations with reversed phase (RP) or hydrophilic interaction chromatography (HILIC) columns and positive or negative MS ionization modes (ie, RP $+/-$, HILIC $+/-$). Peak areas were used as a measurement of feature intensity. For identification, mass-to-charge ratios (m/z) were searched against the Human Metabolome Database³¹ and METLIN,³² using ions $[M + H]^+$, $[M + Na]^+$, $[M - H]^-$ and $[M + FA - H]^-$, with 8 ppm molecular weight tolerance. Where pure chemical standards were commercially available, identification was confirmed by reanalysis of representative samples and pure chemical standards comparing retention times and MS/MS spectra. When standards were not available, MS/MS spectra were acquired when possible and compared against those in mzCloud (www.mzcloud.org) or METLIN. The level of identification was determined as proposed by Sumner et al³³ in line with recommendations of the Metabolomics Standards Initiative which ranks metabolites into four distinct categories: unambiguous identification using pure

TABLE 1 Characteristics of HCC cases and matched control subjects, nested within the EPIC cohort

Variables	HCC cases (n = 129)		Matched controls (n = 129)		P value ^a
Women (n, %)	41	31.8	41	31.8

Liver function score (n, %) ^c					
0	24	18.6	75	58.1	<.0001
≥1	66	51.2	16	12.4	

Note: Missing values were not excluded from percentage calculations, thus the sum of percent values across subgroups may not add up to 100%. Number of cases and controls with missing or unknown variable value: education (controls = 3, HCC = 2), smoking status (controls = 1, HCC = 1), hepatitis infection status (controls = 38, HCC = 38), diabetes status (self-reported, controls = 13, HCC = 11) and liver function score (controls = 38, HCC = 38). The distribution of cases by country is as follows: Denmark = 23, Germany = 32, Greece = 16, Italy = 28, the Netherlands = 4, Spain = 11 and the United Kingdom = 15. Categorical variables are presented as numbers and percentages. Continuous variables are presented as mean and SD.

Abbreviations: HBV, hepatitis B virus; HBsAg, hepatitis B surface antigen; HCC, hepatocellular cancer; HCV, hepatitis C virus; HHCC, human hepatocellular cancer.

^aPaired *t* test for continuous and Fisher exact test for categorical variables were used to calculate *P* value.

^bHepatitis B and/or C seropositivity values were detected using the ARCHITECT HBsAg and anti-HCV chemiluminescent microparticle immunoassays (CMIA; Abbott Diagnostics, France).

^cLiver function biomarkers (ALT, AST, GGT, ALP, albumin and bilirubin) were measured on the ARCHITECT cSystems (Abbott Diagnostics). The liver function score was computed as an indicator of possible underlying liver damage. The score ranges from 0 to 6 and is based on abnormal liver function tests (ALT > 55 U/L, AST > 34 U/L, GGT > 64 U/L for men and >36 U/L for women, ALP > 150 U/L, albumin < 34 g/L, total bilirubin > 20.5 μmol/L; values were provided by the laboratory). For each liver function biomarker, participants with abnormal values (as defined earlier) were assigned a score of 1. Possible liver impairment category was created for the score ≥ 1.

standards (Level 1), identified with a high level of confidence based on chemical features and characteristics (Level 2), identified to a known chemical class (Level 3) and unknown/unidentifiable compounds

(Level 4). For the purposes of this analysis, Levels 1 to 3 are considered identified metabolites, but with varying levels of certainty (ie, unambiguous, highly likely and chemical class only).

2.4 | Additional laboratory measures

In a large subset of subjects, a score of liver function (indicator of underlying liver damage) was computed using additional and already available biomarker measures^{34,35} (details in Table 1 footnotes).

2.5 | Dataset preparation and statistical analyses

A separate analysis was conducted for each data set from the four analytical configurations (ie, RP +/–, HILIC +/–). In each data set, features missing from more than 25% of all samples were excluded to avoid extensive imputation of the data before the paired statistical analysis (see Figure 1 for details). In order to retain a maximum number of complete case-control sets in the statistical analyses, missing values for any feature (features not detected in a given subject) for any feature were replaced with the minimum intensity of that feature in the dataset (Figure 1). To assess differences between

cases and controls, feature intensities were log₂-transformed (to improve data normality) and z-standardized (to better enable comparisons across a wide intensity range), and subsequently entered into conditional logistic regression models from which odds ratios (OR) and 95% confidence intervals (95% CI) were computed. Two main statistical models were applied, (a) a crude model, conditioned on the matching criteria only and (b) a detailed multivariable model with additional adjustments for continuous variables body mass index (BMI, kg/m²), waist circumference (cm), recreational and household physical activity (Met-h/wk), alcohol intake at recruitment (g/d), and categories of lifetime alcohol intake pattern, smoking status and the highest level of education attainment (for categories, see Table 1). The Benjamini-Hochberg correction for multiple testing was applied using the multitest procedure in SAS and a *q* value of ≤0.05 was considered as statistically significant. Additionally, fold change between the median intensity for the cases vs the controls was used to rank the features by their absolute intensity difference. Thresholds for the selection of the most discriminating features for

	RP+	RP–	HILIC+	HILIC–

FIGURE 1 Flow chart of the selection procedures for metabolites and number of annotated compounds for each analytical configuration of the UHPLC-QTOF-MS system. A total of 114 separate compounds (ie, confirmed molecules that consisted of one or more features) were identified from the four data sets. Of these 114 separate compounds, 22 were also detected by more than at least one of the other three profiling methods, leaving a total of 92 unique compounds. Of these 92 compounds, 46 were identified from three distinct categories: unambiguously identified using pure standards (Level 1; *n* = 14), identified to a high level of confidence based on chemical features and characteristics (Level 2; *n* = 23) and identified to a known chemical class (Level 3; *n* = 9). The remaining 46 compounds were not identified, that is, unknown. (1) After Benjamini-Hochberg correction for multiple testing, conditioned on matching factors: age at blood collection (±1 year), sex, study center, time of the day at blood collection (±3 hours), fasting status at blood collection (<3, 3–6 and >6 hours); among women, additionally by menopausal status (pre-, peri- and postmenopausal), and hormone replacement therapy use at time of blood collection (yes/no). (2) After Benjamini-Hochberg correction for multiple testing: matching factors + BMI (kg/m², continuous), waist circumference (cm, continuous), physical activity (Met-h/wk, continuous), alcohol intake at recruitment (g/d, continuous), lifetime alcohol intake pattern (categorical), smoking status (categorical) and attained education (categorical). Please see Tables 2 to 4 for additional details [Color figure can be viewed at [wileyonlinelibrary.com](https://onlinelibrary.wiley.com/doi/10.1002/ijc.33236)]

annotation were based on absolute median fold change of ≥ 1.20 . Additional adjustments for hepatitis infection status (to correct for this established risk factor), self-reported type-2 diabetes at baseline (to correct for potential influence of diabetes-related metabolic dysfunction) and a composite score of liver function (to correct for the extent of liver dysfunctionality and capacity) were applied in supplementary analyses for all identified features.

Sensitivity analyses were conducted excluding first 2 and 4 years of follow-up ($n = 22$ and $n = 43$ cases excluded, respectively) to assess potential reverse causation. For these analyses, a P value ≤ 0.05 was considered statistically significant.

Pearson correlation coefficients were used to assess the correlations between metabolites that were annotated (ie, those at Levels of identification 1-3,³³ but not unknown metabolites). For these same annotated metabolites, we conducted principal component analyses in order to illustrate the separation of profiles from baseline over the timeline of the follow-up period (ie, from baseline recruitment into the cohort to the date of diagnosis) between identified features of cases and controls. In addition, we then constructed a receiver operating characteristics (ROC) curve based on stepwise forward selection of metabolites from the panel of

metabolites that were annotated to Level 1 (ie, the panel of metabolites that were significantly different between cases and controls and unambiguously identified using a pure standard) and those at Levels 1 to 3.³³ The final areas under the ROC curve for the identified discriminant features were obtained using leave-one-out cross-validation.

All statistical tests were two-sided. Analyses were conducted using SAS version 9.3 (SAS Institute, Cary, NC), R version 3.4.3 (Principal Component Analyses) or MetaboAnalyst version 4.0 (Heatmap).

3 | RESULTS

Characteristics of the HCC cases and their matched controls are presented in Table 1. Cases were primarily men, former drinkers and current smokers, and had higher waist circumference, higher prevalence of hepatitis B/C infection and higher degree of liver dysfunction than matched controls. The average length of follow-up was 8.5 years for cases and controls combined and 5.9 years for cases alone, with a maximum follow-up length of 15 years from baseline.

Abbreviations: HCC, hepatocellular carcinoma; MS/MS, mass spectrometry-mass spectrometry; OR, odds ratio.

^aFeatures identified with high confidence and verified by a chemical standard.

^bLevel 1 identified compounds: retention time and MS/MS matches with an authentic chemical standard.³³ Information for compounds identified at Level 2 (identified compounds with high confidence; no standard available/analyzed but matching isotope pattern, MS/MS spectra, and other supporting evidence) is shown in Table 3. Information for compounds identified at Level 3 (compounds identified from a known chemical class) and Level 4 (unidentified compounds) is shown in Table 4.

^cAbsolute fold change between the median intensities of cases to their matched controls.

^dThe ORs represent the risk of HCC per 1 SD of logarithm transformed value. Multivariable adjusted: matching factors + body mass index (BMI, kg/m², continuous), waist circumference (cm, continuous), alcohol intake at recruitment (g/d, continuous), physical activity (Met-h/wk, continuous), categories of smoking status, alcohol intake pattern and education (for categories see Table 1).

^eIndicates that a compound was detected by more than one method. The listed method is the one showing the greatest intensity for the particular compound. Dehydroepiandrosterone sulfate was also detected by RP-; N1-acetylspermidine was also detected by RP+; glycochenodeoxycholic acid was also detected by HILIC+, RP-; glycocholic acid was also detected by RP-; benzylcarnitine was also detected by RP+.

From the combined total of 9206 molecular features provided by the four analytical configurations of the LC-MS, 5229 (ie, 2551 (RP+), 1178 (RP-), 736 (HILIC+) and 764 (HILIC-)) were present in at least 75% of all samples and were exported for statistical analyses (Figure 1). Initially, 333 (RP+), 20 (RP-), 68 (HILIC+) and 14 (HILIC-) features were found to be statistically significantly associated with HCC risk in multivariable models (Supplementary Tables 1A-D, respectively). Excluding the features with a median fold change less than 1.20 resulted in a total of 220 features from the four analytical configurations combined. From these 220 features, 114 individual compounds (ie, confirmed molecules that

consisted of one or more features) were observed in the four data sets (Figure 1) and are visualized in volcano plots (Supplementary Figure 1).

Of the 114 individual compounds, 22 were also detected by at least one of the other three profiling configurations, leaving a total of 92 unique annotated compounds. Each profiling configuration identified at least five unique compounds, highlighting the advantages of applying all four orthogonal analytical configurations for more comprehensive metabolite coverage. Identification was attempted for each of these 92 unique compounds, ranking them according to varying levels of confidence based on the recommendations of the

Abbreviations: HCC, hepatocellular carcinoma; OR, odds ratio.

^aFeatures that are identified at the level of the chemical class (Level 3) or unknown (Level 4).³³

^bCompounds identified at Level 3 (compound from a known chemical class) and Level 4 (unknown compounds) are shown here.³³ Information for compounds identified at Level 1 (retention time and MS/MS matches with an authentic chemical standard) and Level 2 (no standard available/analyzed but matching isotope pattern, MS/MS spectra and other supporting evidence) is shown in Tables 2 and 3, respectively.

^cAbsolute fold change between the median intensities of cases to their matched controls.

^dThe OR values represent the risk of HCC per 1 SD of logarithm transformed value. Multivariable adjusted: matching factors + body mass index (BMI, kg/m², continuous), waist circumference (cm, continuous), alcohol intake at recruitment (g/d, continuous), physical activity (Met-h wk, continuous), categories of smoking status, alcohol intake pattern and education (for categories see Table 1).

^eIndicates that a compound was detected by more than one method, also listed. Data are provided only for the method that showed the greatest intensity for the particular compound: C19H28O3-sulfate (OH-DHEA-S) was also detected by HILIC-ve.

Metabolomics Standards Initiative.³³ Fourteen metabolites were unambiguously identified using pure reference standards (Level 1, Table 2), another 23 compounds were identified with a high level of confidence based on chemical features and characteristics (Level 2, Table 3) and 9 compounds were identified to a known chemical class (Level 3, Table 4), summing to a total of 46 identified metabolites. Pearson correlation coefficients between these 46 identified metabolites are shown in Supplementary Figure 2. The remaining 46 metabolites could not be identified and are listed as unknown (Level 4, Table 4). Intensity means, SD and medians for these 92 compounds are shown in Supplementary Table 2A.

The multivariable-adjusted HCC-risk associations for the 14 metabolites identified at Level 1 are shown in Table 2. Of these 14 metabolites, 5 were inversely associated with HCC risk (*q*-value ≤0.05): retinol (OR = 0.27, 95% CI: 0.16–0.48), dehydroepiandrosterone sulfate (DHEA-S; OR = 0.35, 95% CI: 0.22–0.57), glycerophosphocholine (OR = 0.44, 95% CI: 0.28–0.71), γ -carboxyethyl hydroxychroman (γ -CEHC; OR = 0.56, 95% CI: 0.39–0.81), creatine (OR = 0.56, 95% CI: 0.37–0.83). The remaining 9 metabolites were positively associated with HCC risk: N1-acetyl spermidine (OR = 2.16, 95% CI: 1.38–3.37), isatin (OR = 2.56, 95% CI: 1.53–4.29), *p*-hydroxyphenyllactic acid (HPLA; OR = 2.63, 95% CI: 1.62–4.28), tyrosine (OR = 2.77, 95% CI: 1.58–4.83), sphingosine (OR = 2.79, 95% CI: 1.66–4.71), L,L-cyclo (leucylprolyl) (OR = 3.25, 95% CI: 1.91–5.53), glycochenodeoxycholic

acid (OR = 3.31, 95% CI: 1.99–5.51), glycocholic acid (OR = 4.07, 95% CI: 2.32–7.14) and 7-methylguanine (OR = 6.78, 95% CI: 3.24–14.18).

We additionally conducted ROC discriminant analyses from the panel of the 14 Level 1 identified metabolites. The analyses showed that the discrimination between cases and controls was largely driven by retinol, DHEA-S, L,L-cyclo(leucylprolyl) and 7-methylguanine. Additional ROC analysis using leave-one-out cross-validation for these four independent metabolites indicated a 84.6% discriminatory accuracy, compared to a 85.0% discriminatory accuracy when all 14 Level 1 identified metabolites were modeled. This method of validation was chosen to avoid likely statistical power issues that would arise from splitting the main data set into discovery and validation subsets, each of which would include a smaller number of cases. Conversely, we applied the leave-one-out cross-validation approach to the identified metabolites rather than at the stage of feature selection, as would be the case in a true validation setting with training and validation subsets. Thus, the area under the curve estimate is likely to be biased.

Multivariable-adjusted HCC-risk associations for the 23 Level 2 metabolites (largely phosphatidylcholines (PC), lysophosphatidylcholines (lysoPC) of various chain lengths, diacylglycerols, two bilirubin metabolites and benzoylcarnitine) are shown in Table 3. Multivariable-adjusted HCC-risk associations for Level 3 (some glycerophosphocholines and C19 steroid sulfates) and Level 4 compounds are shown in Table 4.

(A) Score plots of PC analyses differentiating cases and controls

(B) Plot of scores on PC1 versus follow-up time

FIGURE 2 Principal component (PC) analyses based on metabolites associated with HCC risk for (1) the 46 metabolites associated with HCC risk and identified at Levels 1 to 3³³ and (2) the 14 metabolites associated with HCC risk and identified at Level 1 only, that is, unambiguous identification using pure standards.³³ HCC cases are shown by green circles and matched controls by mauve triangles. A, Score plots of PC analyses differentiating cases and controls; B, plot of scores on PC1 vs follow-up time (all years, number of HCC case and matched control sets = 129; and excluding cases with 4 or less years of follow-up, number of HCC case and matched control sets = 87); C, relative contributions of identified metabolites to PC1 and PC2. For A1, the proportion of variability is 29.86% for PC1 vs 11.12% for PC2. For A2, the values are 29.18% for PC1 and 11.16% for PC2 [Color figure can be viewed at wileyonlinelibrary.com]

(C) Relative contributions of identified metabolites to PC1 and PC2.

(2) 14 metabolites identified at level 1

FIGURE 2 (Continued)

Results for the crude models conditioned on the matching criteria only are shown in Supplementary Table 2B. Supplementary analyses with additional adjustments for hepatitis B and/or C infection status, self-reported diabetes status at baseline (Supplementary Table 2C)

and a score of liver functionality within the multivariable analysis model did not materially alter the findings (Supplementary Table 2D). In sensitivity analyses, the observed associations, particularly for Levels 1 and 2 compounds, were unaltered after exclusion of case-

control pairs where the case participant was diagnosed within either the first 2 or 4 years of follow-up (Supplementary Table 2E).

We conducted two principal component analyses: one based on the 46 metabolites identified to Levels 1-3 and a second one restricted to the 14 metabolites identified to Level 1 (Figure 2). These analyses show distinct differences between metabolic profiles of HCC cases compared to control participants, up to 10 years prior to diagnosis. Additional sensitivity analyses excluding case-control pairs where the case was diagnosed within the first 4 years of enrollment into the cohort did not alter the clear distinction in metabolite profiles between HCC cases vs controls (Figure 2).

Detailed information on metabolite identification with chromatograms and spectra is provided in Supplementary Materials (Identification of Metabolites).

4 | DISCUSSION

In this case-control study nested within a large, multinational observational prospective cohort, we applied a powerful MS-based untargeted metabolomics approach to explore metabolic perturbations underlying HCC development. The cases in our observational cohort were enrolled at the baseline period (ie, data and blood samples collected upon recruitment) when the participants were under apparent health. Later, at various time points postrecruitment, some of the cohort participants were diagnosed with HCC. Thus, the cases in our study originate from different time points after baseline recruitment. In the subgroup of cases who were diagnosed closer to baseline, it is likely that the processes of HCC were already underway even though undiagnosed, possibly within a background of other liver pathologies. However, in the subgroup of subjects where the HCC was diagnosed later on during the cohort follow-up, the baseline blood samples are likely to have been collected in the absence of HCC or at its earlier stages. Due to the liver's central metabolic roles, it is thought that metabolic disturbances are early events in the development of chronic liver diseases and HCC.³⁶ This premise underscores the rationale behind our study, conducted within the setting of an observational prospective cohort. We were able to determine 92 distinct metabolites whose relative concentrations were different between HCC cases and their matched controls in prediagnostic blood samples. Of these 92 compounds, we were able to identify 46 of which 14 were unambiguous (Level 1³³) and an additional 23 and 9 with high degrees of confidence (Levels 2 and 3, respectively³³). We show, using principal component analyses, that the differences between HCC cases and controls are apparent as far back as 10 years prior to diagnosis, even with exclusion of cases diagnosed within the first 2 or 4 years of follow-up. We observed perturbations in general classes of metabolites, such as amino acids and bile acids, but also in xenobiotics as indicators of lifestyle exposures, as well as some compounds with purported roles in immune function, hormone metabolism, gut microbiome activity and liver fat content—underscoring the complexity of metabolic disturbances in HCC development. The metabolites identified may be involved directly and/or be markers of

various exposures associated with cancer risk. Moreover, we accounted for established etiologies of HCC such as hepatitis infection, high alcohol consumption and smoking in our statistical analysis models. Our observations were mostly unchanged with these adjustments, suggesting that metabolic perturbations in HCC may be largely similar, irrespective of the main underlying etiology of the tumor.

Of the 46 metabolites that we could identify in our study, 14 were confirmed using authentic chemical standards. Several of these appear to be related to dietary and lifestyle habits. Specifically, we observed inverse HCC-risk associations for retinol (biologically active form of vitamin A) and γ -CEHC (a product of liver metabolism of γ -tocopherol).^{37,38} Retinol has a plausible role in liver carcinogenesis (eg, modulation of immune function, cell growth).³⁹ Its potential association with liver cancer has been previously assessed in two prospective studies, a Finnish cohort of male smokers⁴⁰ and a cohort of Chinese men,⁴¹ both of whose findings are in line with our own observations. γ -CEHC shows some antioxidant and anti-inflammatory properties, similar to γ -tocopherol.^{38,42} It has been purported as a treatment of nonalcoholic steatohepatitis, a precursor of liver cirrhosis and risk factor for HCC development,⁴³ but little other data are available on any specific HCC protective roles for this compound.

We also observed inverse HCC-risk associations for glycerophosphocholine, several lysoPCs, creatine and DHEA-S, a steroid hormone. Interestingly, decreased glycerophosphocholine level has been observed to be predictive of higher circulating vitamin D concentrations,⁴⁴ which would be in line with our earlier observation of a strong inverse HCC-risk association with higher circulating vitamin D in these same subjects.⁴⁵ Inverse HCC-risk associations with higher circulating lysoPCs are consistent with other reports.^{10,15,46} The observed association with creatine may reflect decreased liver functionality and lower creatine synthesis in HCC development, although it has also been ascribed to both antioxidant and oxidative properties.⁴⁷ Our observation of an inverse association with DHEA-S is intriguing because androgen receptor activity, with which DHEA-S interacts, has been implicated in HCC development,^{48,49} and the promotion of HCC by androgens has been put forward as one explanation for its higher incidence in men.⁵⁰ On the other hand, liver cirrhosis has been linked to hormonal imbalances between estrogens and androgens resulting in a higher relative concentration of estrogens.⁵⁰ Some animal data even suggest that DHEA-S may protect against development of liver lesions.⁵¹ Thus, our observations merit more detailed assessment of hormonal factors and circulating concentrations.

In an earlier study based on NMR spectroscopy within the same subjects, we found a positive HCC-risk association for the amino acid tyrosine.¹⁶ Similar observations have been made in a Korean prospective cohort²⁵ and the Alpha-Tocopherol, Beta-Carotene Cancer Prevention (ATBC) cohort composed of Finnish male smokers.¹⁸ Our observations in the present study were similar for tyrosine along with HPLA, a tyrosine metabolite. Tyrosine is found in several foods (eg, cheeses, which incidentally have also been associated with increased HCC risk in our data⁵²) and is produced endogenously from phenylalanine. Tyrosine levels are known to be altered in liver disease⁵³ while

HPLA has demonstrated carcinogenic activity after long-term subcutaneous injection in mice,⁵⁴ and its urinary levels have been observed to be elevated in breast cancer patients.⁵⁵

Positive HCC-risk associations were also observed for isatin, L, L-cyclo(leucylprolyl), N1-acetylspermidine and sphingosine—although, very little is known about any physiological roles for these compounds in HCC development. Isatin is a biologically active endogenous metabolite with antioxidant and antiviral effects⁵⁶—properties that may be considered as cancer protective rather than explanatory of our observed positive HCC-risk association. However, isatin can also be derived from gut microbial metabolism,⁵⁶ and we can speculate that its higher circulating concentrations in HCC cases may be due to leakage from the gut across a dysfunctional colonic barrier, something which we have previously observed in the same HCC cases.⁵⁷ For its part, L, L-cyclo(leucylprolyl) has been associated with increased liver fat content in a German general population sample,⁵⁸ possibly suggesting a link with fatty liver disease in some of our cases. There is sparse data on the possible roles of N1-acetylspermidine (a polyamine) and sphingosine (an aminodiol which can form ceramides, parent structures to sphingolipids) in HCC. The former may be affected by liver functionality⁵⁹ and its serum levels have been shown to be higher in liver cancer patients,⁶⁰ whereas sphingosine has been observed to be elevated in chronic liver diseases, such as NAFLD and chronic hepatitis C infection.⁶¹ Thus, alterations in circulating levels of these metabolites may be indicative of liver dysfunctionality and possibly early HCC development.

Another interesting observation from our study is the positive HCC-risk association of glycochenodeoxycholic acid and glycocholic acid—both of which are glycine conjugates of primary bile acids formed in the liver.⁶² Their circulating concentrations have been shown to be increased in various liver diseases, including HCC.^{10,15,25,46,63,64} In general, proinflammatory and carcinogenic properties have been ascribed to bile acids and as such they have a plausible role in HCC development.⁶⁵ Perturbations in serum bile acid metabolism have been previously observed in other settings, such as in largely hepatitis-positive Chinese populations,^{66,67} and specifically for glycochenodeoxycholic acid and glycocholic acid in the ATBC cohort.¹⁸ The liver is central to bile acid metabolism, and hence perturbations in bile acid profiles may be among the earliest indicators of HCC development. A more detailed analysis of potential alterations in the profiles of various bile acids in the different phases of this disease would be of great interest.

In our observations, the metabolite most strongly positively associated with HCC risk is 7-methylguanine, an indicator of exposure to methylating agents. It has previously been observed to be higher in the urine of smokers⁶⁸ and those with unhealthy lifestyle habits⁶⁹—exposures which have also been associated with increased HCC risk in our cohort.^{34,70} Higher levels of this compound have also been associated with an increased risk of total mortality in a cohort of male smokers.⁷¹ It may thus be a metabolite related to smoking exposure, and so further study of its potential role in HCC development is warranted.

Taken together, our findings relate to dietary and lifestyle exposures that may be potentially HCC promoting, as well as to liver dysfunctionality, which is central to the development of HCC and other liver diseases.

A major limitation of our study nested within a prospective cohort is the lack of information on the existence and severity of any other liver diseases leading up to HCC development. For example, information on existing liver cirrhosis would have been helpful in further characterizing our HCC cases between cirrhotic and noncirrhotic pathways of HCC development. A related critique of our study design is the lack of a second control group composed of subjects with liver diseases. We do not have any access to relevant clinical information on liver diseases among our >520 000 cohort participants. However, such a control group would have allowed us to better understand transitions from existing liver pathologies toward early HCC. Although this is a reasonable assertion for studies designed to assess clinical surveillance for HCC in higher risk populations, it is less relevant to prospective cohorts geared toward exploring cancer etiology in the general population. Nevertheless, we have addressed these concerns by making multivariable statistical adjustments for main HCC risk factors in our study population. These adjustments did not meaningfully alter our findings, suggesting that different HCC etiologies—whether related mainly to chronic hepatitis infection, alcohol abuse, smoking or obesity—may have a large degree of overlap in terms of their metabolic consequences on the liver and hence transitions toward development of HCC. Patient cohorts comparing HCC cases to control subjects with liver disease provide vital insight toward risk stratification for HCC screening and identification of diagnostic biomarkers, they have to be distinguished from findings such as ours, which are based on large-scale prospective cohort studies and which bring understanding of potential risk factors and metabolic perturbations in HCC development. Another limitation is our lack of information on any tumor-staging criteria at diagnosis or treatments postdiagnosis. We did not consider survival and we cannot discount some degree of confounding by stage at diagnosis—but it must be noted that biological samples in our cohort were collected at recruitment, prediagnosis. In randomized clinical trials, allocation of exposure and prognostic factors would be random, but collection of data and biological samples in the cases is not likely to be prediagnostic. Studies with these different designs each provide crucial insight into the development of this lethal cancer, and should all be part of the evidence base for establishment of guidelines toward HCC prevention, as well as discovery of biomarkers for early diagnosis. We consider the fact that our HCC cases were derived from within an observational cohort with prediagnostically obtained biological samples and detailed confounder data as a major advantage that minimize recall and reverse causality biases adding another degree of robustness to our observations. At the same time, we acknowledge that our study design does not allow insight into transitions from existing liver pathologies toward HCC.

Another important design advantage of this work is that we applied an agnostic metabolomics approach using high-resolution mass spectrometry with four complementary analytical configurations,⁷²

enabling us to maximize the number of metabolites measured for a more complete assessment of metabolic profile changes between the HCC cases and their matched controls. We identified many metabolites with very high confidence, and we also observed a number which we could not identify despite our best efforts. We believe that the high number of metabolites observed to be associated with HCC risk, both identified and unknown, highlights the depth of metabolic perturbation in this disease. The magnitude of some of the risk associations for the unidentified metabolites, whether inverse or positive, shows that we still have much to learn about the processes of HCC development. The unidentified metabolites provide considerable potential for discovery of additional novel exposure, diagnostic and prognostic biomarkers in other studies. Our findings on specific identified metabolites and metabolic pathways involved in HCC development may be followed up with experimental studies to more carefully query their functionality and mechanisms of action. Additionally, it would be of great interest to determine whether any of our observed metabolites may serve as early diagnostic markers.

In summary, we show statistically significant associations between 46 identified metabolites, which could be either directly involved in HCC development or be the consequence of liver dysfunction caused by tumorigenesis in the liver. Our observations, based on prediagnostically collected blood samples, contribute toward a more in-depth understanding of HCC risk factors and underlying mechanisms of HCC development. They contribute to the evidence base that may be used toward public health guidelines for HCC prevention, but they should also be replicated in other prospective cohorts from different world regions with emphasis on comparing metabolic changes over time from the earliest phases of HCC development.
